RESPIRATION AND GASEOUS EXCHANGE

TISSUE RESPIRATION

This is the breakdown of food substances to release energy. It occurs using enzymes. The major food respired (respiratory substrate) is a carbohydrate (glucose). Other compounds like lipids and proteins are converted into a carbohydrate before they are respired.

The energy released is stored as ATP (Adenosine tri phosphate).

ATP is highly energy rich compound formed from ADP (Adenosine di phosphate) and inorganic phosphate, i.e.

ADP + Pi $\longrightarrow$ ATP

If the energy stored as ATP is required by the body, ATP is suddenly broken down into ADP and Pi to release energy for the body activities i.e.

ATP $\xrightarrow{\text{ATPase enzyme}}$ ADP + Pi + energy

Uses of energy in the body

- Maintaining blood circulation
- Bring about breathing movement
- For producing sound
- Transmission of nerve impulses from one part to another.
- Synthesis of blood proteins
- Maintaining the constant blood temperature
- Cell division either mitosis or meiosis leading to growth
- Active transport of materials into or outside the cell.
- Secretion of various materials like hormones, enzymes, etc.

Stages of respiration

Respiration occurs in a series of reaction which are divided into 2 stages

1. **Glycolysis**

It involves breaking down of six carbon compounds (glucose) into 2 small 3 carbon compounds. This occurs in the cell cytoplasm.

2. **Krebs cycle**

It involves the breaking down of 3 carbon compounds further to release more energy than glycolysis. It occurs in the mitochondria.

Types of respiration.

1. Aerobic respiration.
2. Anaerobic respiration

AEROBIC RESPIRATION

This is the breakdown of food to release energy in presence of oxygen, forming energy, Carbon dioxide and water. It is the most efficient process by which energy is produced because there is complete breakdown of food and it therefore produces more energy.

Equation for aerobic respiration

$$C_6H_{12}O_6 + 6O_2 \longrightarrow 6CO_2 + 6H_2O + \text{Energy}$$

Glucose oxygen Carbon dioxide water

The Carbondioxide produced diffuses from the tissues into the blood and it is transported to the lungs for expiration through the trachea and nostrils. In plants the Carbondioxide produced is

either lost to the atmosphere through stomata on leaves or lenticels in stems or used in photosynthesis to produce food.

EXPERIMENT TO DEMOSTRATE THAT LIVING ORGANISMS USE OXYGEN IN AEROBIC RESPIRATION

Materials:
Conical flask
Delivery tube
Beaker
Sodium hydroxide solution
Water
Germinating seeds

Procedure:

- Some germinating seeds are placed in a conical flask in which a test tube containing sodium hydroxide is enclosed.
- A delivery tube is then connected to the conical flask with one end connected to a beaker containing water.
- The setup is left to stand for 2 hours and observations are made on the level of water in the delivery tube.

Diagram of Setup
(leave 6 lines for the diagram)

Observation:
After 2 hours, water is seen to have risen in the delivery tube.

Conclusion:
Oxygen is used in aerobic respiration.

Explanation:
As the seeds respire, they use oxygen and produce CO_2. However, the CO_2 is absorbed by the sodium hydroxide solution thus it's not added back to the air in the flask hence there's a decrease in the original volume of air in the flask.

EXPERIMENT TO SHOW THAT LIVING ORGANISMS LIBERATE CO_2 DURING AEROBIC RESPIRATION

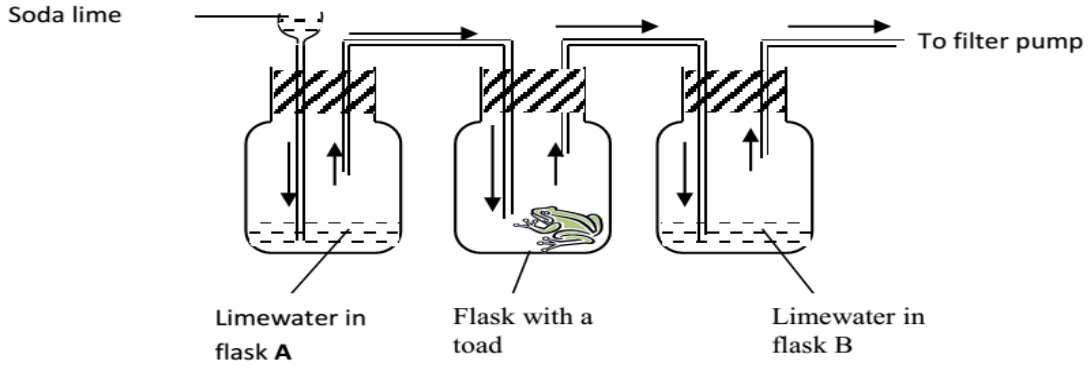
Materials

- Soda lime (sodium hydroxide),
- Lime water,
- Filter pump,
- Toad ,
- Two delivery tubes,
- Three flasks and Corks.

Procedure

- A toad is used as an aerobe and the experiment is fixed as shown below and left to stand for 40 minutes.
- The purpose of sodium hydroxide is to absorb CO_2 from the incoming air.
- Lime water in flask A is used to confirm the absence of CO_2 in the incoming air.
- Lime water in flask C is used to test for the presence of CO_2 in exhaled air.
- The filter pump ensures one direction of air.

Setup



Observation

Limewater in flask B turned milky while that in flask A remained clear.

Conclusion

The living organism gives out Carbondioxide during respiration.

Experiment to show that energy (heat) is released by germinating seeds during Aerobic respiration

Materials:

- Vacuum flask,
- Germinating seeds,
- Cotton wool and
- Thermometer.
- Sodium hypochlorite solution

Procedure

-The seeds are socked in water for 24 hours.

-One group of seeds is then killed by boiling them in water.

-Both sets of seeds are socked in sodium hypochlorite solution for 15 minutes in order to kill any bacterial and fungal spores.

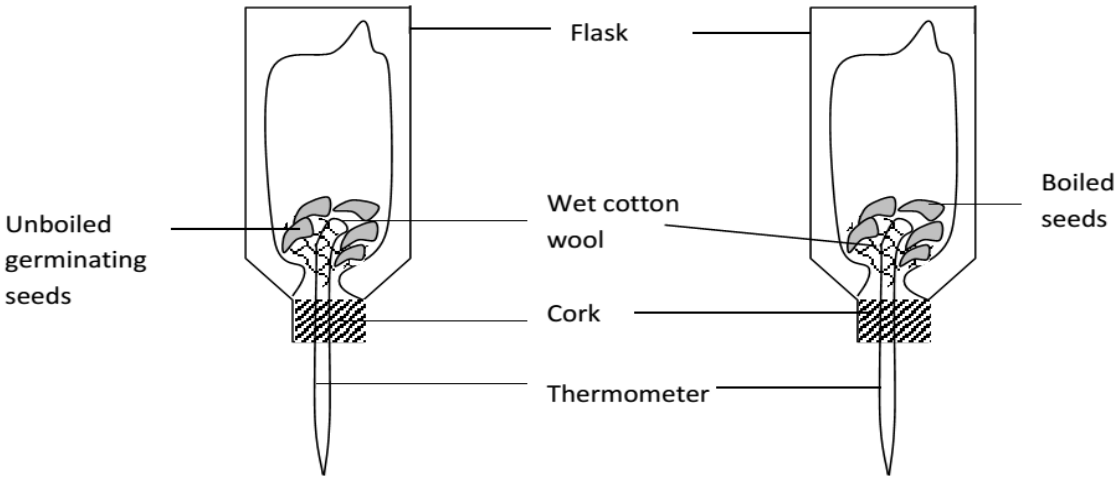
-Place moist germinating seeds in one flask and the boiled seeds in another flask.

-Insert a thermometer in each of the flasks plugged with cotton wool.

-Fix the two flasks on a retort stand in an upside down position so that the seeds are near the thermometer bulb as shown below.

-Leave the setup to stand for three days

Setup



Observation

The temperature in the germinating seeds rises. That of the boiled seeds remains constant.

Conclusion

Germinating seeds give out heat during aerobic respiration.

Explanation

During germination oxygen is absorbed to carry out respiration, which gives out energy in form of heat.

ANAEROBIC RESPIRATION

This is the breakdown of food to release energy in absence of oxygen.

In this process food is not completely broken down, hence little energy is released.

This process releases Carbondioxide, energy and lactic acid in animals or ethanol in plants.

Anaerobic respiration in plants

When plants respire without oxygen, glucose is broken down into ethanol, carbondioxide, water and energy.

$$\underset{\text{(Glucose)}}{C_6H_{12}O_6} \xrightarrow{\text{enzyme}} \underset{\text{(Ethanol)}}{C_2H_5OH} + CO_2 + \text{Energy (118kj)}$$

Little energy is produced, much of it still locked in the partially broken ethanol.

Anaerobic respiration in yeast

- The form of anaerobic respiration carried out by yeast is known as fermentation.
- Fermentation is any form of anaerobic respiration in solution form.
- It leads to production of ethanol, CO_2 and energy which is a chief product. The enzyme involved is zymase enzyme.

$$\underset{\text{(Glucose)}}{C_6H_{12}O_6} \xrightarrow{\text{enzyme}} \underset{\text{(Ethanol)}}{C_2H_5OH} + CO_2 + \text{Energy (118kj)}$$

Anaerobic respiration in Animals

When animals respire without oxygen, glucose is broken down to lactic acid, carbondioxide, and energy.

Oxygen debt

During vigorous exercise, the oxygen supply to muscles may not be enough to meet the energy demands. In the process lactic acid accumulates. As a result the rate of breathing of the individual increases even after an exercise to provide extra oxygen required to oxidize the accumulated lactic acid to CO_2, water and energy.

In this condition the organism is said to be in an oxygen debt. **Oxygen debt** therefore is the amount of oxygen needed to break down the accumulated lactic acid in muscles after vigorous exercises.

Graph showing change in lactic acid and concentration during and after exercise

(Leave 7 lines for a graph)

Lactic acid increases rapidly during an exercise till the end. This is due to increased rate of anaerobic respiration due to lack of enough oxygen supply.

At the end of the exercise, lactic acid content in muscles drops suddenly because it is being oxidized to CO_2, water and more energy in the liver. The oxygen used in breaking down this lactic acid is attained by breathing deeply.

Application of anaerobic respiration(fermentation)

- The process is commercially used in beer brewing to produce alcohol
- It is also used in baking of bread to raise dough.

Experiment to show that CO_2 is given off during anaerobic respiration/fermentation

Materials:

- Two test tubes,
- Delivery tubes,
- Yeast,
- Glucose,
- Oil and
- Lime water.

Procedure

-Boil about 20 cm^3 of glucose solution ***to drive out oxygen*** from it. Allow it to cool to room temperature.

-Add a layer of oil over glucose solution to prevent oxygen from dissolving in it.

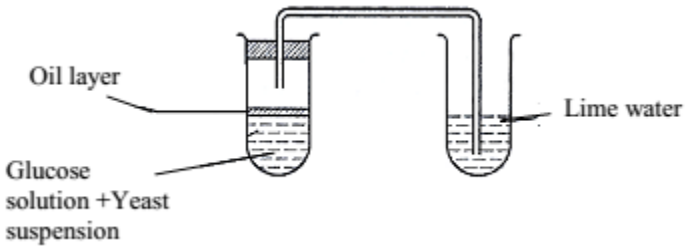
-Add a small quantity of yeast suspension to the glucose solution using a pipette.

-Pour limewater in one test tube.

-Using a delivery tube and rubber bangs fix the delivery tube in the test tube as shown below.

-Leave the experiment to stand in a warm place for an hour.

Setup



-Set up a control experiment in the same way but using a boiled yeast suspension or without yeast or without glucose.

Observation

Bubbles of a gas are seen in limewater and limewater turns milky.

Conclusion

Carbon dioxide is produced during anaerobic respiration.

Explanation

Yeast breaks down glucose in absence of oxygen to produce ethanol, CO_2 and some heat.

The CO_2 produced turns lime water milky.

Experiment to show that heat is liberated during fermentation of yeast OR

Experiment to show the production of energy in absence of oxygen (anaerobic respiration)

Materials:

- 10% glucose solution
- 10% yeast suspension
- 2 vacuum/thermos flasks
- 2 thermometers

- ❖ Cooking oil
- ❖ Cotton wool
- ❖ Water bath

Procedure:

-100cc of glucose solution is boiled in a beaker so as to drive out any dissolved oxygen and then allowed to cool.

-50cc of glucose solution is each poured in each flask and small quantities of oil are added to prevent entry of oxygen into the glucose solution.

-Yeast solution is added below the oil layer of one of the flasks using a dropper/pipette.

-A thermometer is placed in each flask and kept in solution with cotton wool as shown below.

-The thermometer readings are recorded hourly at intervals for some time.

Observation:

After some time, the temperature rises in flask A while in B, the temperature remains the same.

Conclusion:

Heat is liberated during fermentation of yeast.

Explanation

The temperature rises in flask A due to anaerobic respiration of glucose by producing heat.

In B, there's no yeast to respire anaerobically hence no heat is produced.

Similarities between aerobic and anaerobic respiration

1) Both require glucose as a raw material.
2) Both produce energy.
3) Both produce Carbondioxide.
4) Both take place in living cells.

Differences between aerobic and anaerobic respiration

Aerobic respiration	Anaerobic respiration
A common mode of respiration in both plants and animals	Rare process limited to few plants and animals
Produces more Carbondioxide	Produces less Carbondioxide.
Occurs throughout life	Occurs temporary in very active muscles
Liberates large quantities of energy	Liberates less energy
Products are water, Carbondioxide and energy	Products are Carbondioxide, energy and alcohol or lactic acid.
Complete breakdown of food	Incomplete break down of food.
Oxygen is used	Oxygen is not used.

Respiratory Quotient:

This is the ratio of CO_2 produced to oxygen used:

$$RQ = \frac{CO_2 \text{ produced}}{O_2 \text{ used}}$$

Importance of respiration

1) Respiration produces energy that is used to run the various activities in the body.

2) It is exploited commercially in baking, brewing and making of dairy products such as cheese, yoghurt and butter.

Similarities between respiration and photosynthesis

1) Both take place in living cells.
2) Both involve enzymes.
3) Both involve oxygen, Carbondioxide and glucose.
4) Both involve energy.

Differences between respiration and photosynthesis

Respiration	Photosynthesis
Oxygen is absorbed	Oxygen is released
Carbondioxide is released	Carbondioxide is absorbed
Takes place in light and darkness	Needs light to take place
Energy is released	Energy is absorbed
Does not require chlorophyll	It requires chlorophyll
Take place in plants and animals	Takes place in plants only.

GASEOUS EXCHANGE

This is the exchange of respiratory gases between the organism and the environment. It takes place across specialized surfaces called respiratory surfaces. Gaseous exchange helps an organism to get rid of CO_2 produced during respiration within cells and at the same time obtain oxygen needed for aerobic respiration to occur.

Note:*Breathing is an* ***active process*** *involving movement of air in and out of the body whereas gaseous exchange is a* ***passive process*** *involving passage of air through respiratory surfaces/gaseous exchange surfaces.*

Characteristics of a good respiratory surface

Respiratory surfaces are sites where gaseous exchange takes place in the body of the organism. Respiratory surfaces possess the following characteristics:

1) They have a large surface area to volume ratio to enable rapid diffusion of gases. This is achieved by folding or branching of structures to form alveoli in lungs, gill filaments in the gills and tracheoles in insects.
2) They are moist to allow easy diffusion of gases.
3) They are thin walled to reduce on the distance over which diffusion has to take place.
4) They have a good network of blood capillaries for easy transportation of gases to the respiring tissues.
5) They are well ventilated to maintain a high concentration gradient that favours diffusion of gases.

Note; respiratory surfaces of insects are not supplied with a network of blood capillaries because the blood of insects does not transport gases. The gases are transported in the tracheole tubes.

GASEOUS EXCHANGE IN PLANTS

Plants do not have a special respiratory surfaces for gaseous exchange. They use stomata of the leaves and lenticels of the stems for gaseous exchange.

Gases circulate in the plant by simple process of diffusion due to abundant large intercellular spaces that make diffusion faster.

Plants do not need special respiratory surfaces and blood transport system because:

i) They use CO_2 from respiration for photosynthesis thus preventing accumulation.
ii) Plants produce oxygen as a bi-product of photosynthesis which is then used in respiration.
iii) Plants have numerous stomata and lenticels that favour fast gaseous exchange.
iv) They have large intercellular spaces that favour fast circulation of gases without blood.
v) They have low demand for oxygen due to their low metabolic rate because they are less active since they are immobile.

Gaseous exchange in simple organisms

Small organisms like amoeba, paramecium, hydra and jellyfish have a large surface area to volume ratio.This facilitates a faster rate of diffusion to ensure that all body tissues are supplied with respiratory gases.In such organisms gaseous exchange takes place over the whole body surface. Because of their small size, diffusion alone is enough to transport oxygen in to and carbondioxide out of their bodies.

Larger organisms such as insects and vertebrates have a small surface area to volume ratio. In these organisms, gaseous exchange takes place in a specialized regions of the body known as a respiratory surfaces.

Examples of respiratory surfaces and corresponding respiratory organs

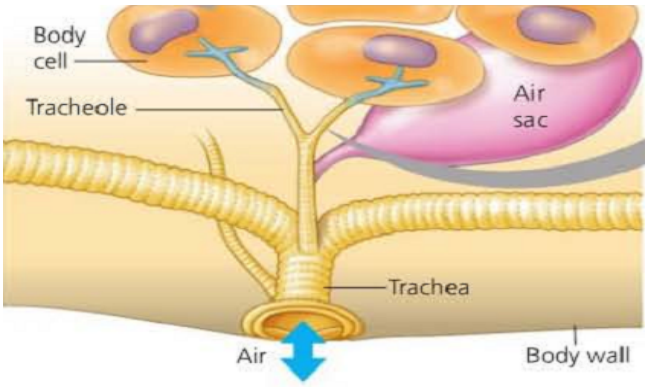
Animal	Respiratory organ	Respiratory surface
Amphibians	Lungs	Alveolus
Amphibians	Skin	Skin surface
Amphibians	Buccal cavity	Buccal cavity epithelium
Birds	Lungs	Alveolus
Fish	Gills	Gill filaments
Insects	Tracheal system	Tracheoles
Mammals	Lungs	Alveolus
Tadpoles	Gills	Gill filaments

NB: the movement of gases and water to and from respiratory surface is called ventilation (breathing).

GASEOUS EXCHANGE IN INSECTS

The respiratory organs of insects consist of a network of tubes known as tracheal tubes, which make up the tracheal system.

The tracheal system of insects



Ventilation mechanism

Inhalation:

- When the abdominal wall expands, the internal pressure reduces and the volume increases.
- This forces air containing oxygen in to the insect through the spiracles, to the trachea and then the tracheoles.
- Between the tracheoles and muscles of the insect, gaseous exchange occurs with oxygen entering in to the tissues and CO_2 released from tissues, diffusing into the fluid in the tracheoles

Exhalation:

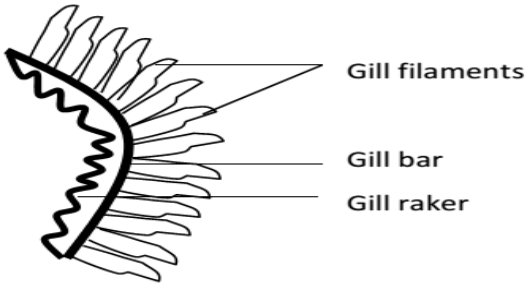
Abdominal wall contracts, internal volume decreases while pressure increases, forcing air with a high concentration of carbon dioxide in the tracheoles out of the insect through the spiracles.

GASEOUS EXCHANGE IN FISH

Fish uses water as a medium of gaseous exchange and their respiratory surfaces are the gill lamellae of internal gills.

Fish absorb dissolved oxygen from water by use of gills. In most fish there is a pair of gills on each side of the body and in bony fish the gills are covered by a gill plate called the operculum.

Structure of the gill



Parts of the gill:

1. **Gill bar**: this provides an attachment and support to the gill filaments.
2. **Gill raker**: These are hard projections from the gill bar.
   - They trap food suspended in water.
   - They protect the gill filament by filtering out sand particles in water before reaching the gill filament.

3. Gill filaments:

These are sites of gaseous exchange in the fish.

- They are finger-like projections that increase the surface area for gaseous exchange.
- They have a network of capillaries whose blood moves in the opposite direction with water (counter current flow) to maintain a high concentration gradient by carrying away the diffused gases.
- Filaments have a thin membrane
- They are well ventilated.
- They are numerous to increase the surface area for gaseous exchange.

Mechanism of ventilation in bony fish

Inward movement of water

- The fish closes the operculum (gill cover) and opens the mouth.
- It then lowers the floor of the mouth cavity. This increases volume of the mouth cavity and lowers its pressure below that of the surrounding water.
- The mouth then opens to let in water into the mouth cavity (buccal cavity)
- It then closes the mouth and raises the floor of the mouth.
- This decreases the volume and increases the pressure in the buccal cavity.
- Meanwhile the gullet is closed.
- This forces water to flow into the gill chamber.
- As water passes over the gill filaments, gaseous exchange takes place i.e. oxygen diffuses into blood while CO_2 diffuses from blood into the water.

Out ward movement of water:

- The operculum muscles relax and the operculum opens, then water flows out.
- Meanwhile the buccal floor is still raised and the mouth is still closed.
- The buccal floor then lowers to repeat the cycle.

GASEOUS EXCHANGE IN AMPHIBIANS

a) Tad pole

- Tad poles first use external gills and later internal gills as surface of gaseous exchange.
- The tad pole takes in water through the mouth and the water passes over the gills and then out of the body through the gill slits.
- The oxygen diffuses from the water into the blood while CO_2 from blood into water.

b) Adult amphibians

In adults gaseous exchange takes place through the;

1. Skin.
2. Lining of the mouth cavity.
3. Lungs.

Amphibians depend mostly on their skin and buccal cavity for their gaseous exchange while in water. Lungs are only used when on land or when the water dries and the amphibian has to remain in mud.

1. The skin

The skin is thin walled, moist and has a good network of blood capillaries.

On land, the atmospheric oxygen dissolves in the layer of moisture and then diffuses across the skin into the blood.

At the same time, CO_2 diffuses from the blood into the atmospheric air.

In water, the oxygen dissolved in it, diffuses from the water across the skin into blood. CO_2 diffuses from blood into water.

2. The buccal cavity

The buccal cavity has a thin lining which is kept moist. It also has a good network of blood capillaries. The cavity is ventilated in the following ways.

During inhalation:

- The mouth closes and opens the nostrils.
- The mouth floor lowers.
- This increases the volume and reduces the pressure within the buccal cavity.
- Air enters from the atmosphere through the nostrils into the buccal cavity.
- Oxygen diffuses through the thin cavity membrane into blood while Carbondioxide diffuses from blood into the buccal cavity.

During exhalation:

- The mouth floor raises.
- This reduces the volume and increases the pressure within the mouth cavity.
- Air then moves out to the atmosphere through the nostrils.

3. The lungs

- The lungs consist of sacs supplied by a good network of blood capillaries.
- They have a large surface area.
- They are supplied with a lot of blood capillaries
- It is thin walled.

Inhalation:

- The mouth closes and the nostrils open.
- The mouth floor lowers.
- This increases the volume and reduces the pressure within the buccal cavity.
- Air enters through the nostrils into the buccal cavity.
- The nostrils close, and raises the floor of the buccal cavity.
- This reduces the volume of the buccal cavity and increases its pressure, higher than that of the lungs.
- It opens the glottis and air moves from the mouth cavity into the lungs through the trachea.
- Oxygen diffuses from the lungs into blood and Carbondioxide from the blood into the lungs.

Exhalation:

- The pressure in the lungs increases.
- The floor of the mouth cavity lowers to increase its volume and lower its pressure.
- Air moves from the lungs to the buccal cavity.
- The valve to the lungs (glottis) closes and nostrils open.
- The floor of the mouth is then raised.
- This increases the pressure and lowers the volume in the buccal cavity.
- Waste air is forced from the buccal cavity through the nostrils to the atmosphere

GASEOUS EXCHANGE IN BIRDS

Due to metabolic rate, birds need high supply of oxygen and an efficient gaseous exchange mechanism.

The respiratory system is made up of lungs and air sacs.

During inhalation, air enters through the trachea, bronchus to the posterior air sac, to the lungs, then to the anterior air sac and finally to the exterior (atmosphere) through the trachea.

GASEOUS EXCHANGE IN MAMMALS e.g. man

The respiratory organs in man are lungs and the respiratory surfaces are the sac like structures called alveoli.

The respiratory tract (air passage)

Air enters through the nostrils into the nasal cavity where it is warmed to body temperature.

It moves to the back of the mouth(pharynx) then to the larynx, to the trachea, to the bronchus, bronchioles and lastly to the alveolus of the lungs.

Dust and germs inhaled from the atmosphere are trapped in mucus and are moved by the beating action of cilia in the trachea towards the back of the mouth.

This prevents dust and germs from entering the lungs. Therefore, by the time air reaches the lungs it is dust and germ free, warm and moist.

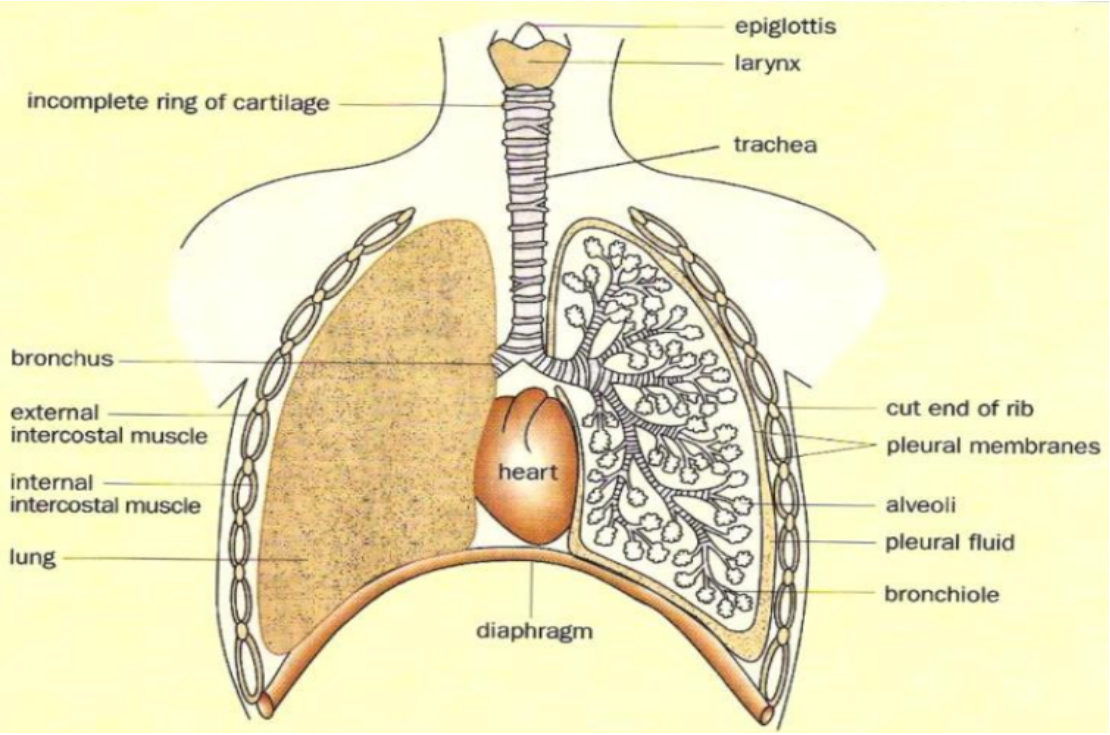
The trachea

This is a tube running from the pharynx to the bronchus. It is always kept open by the circular rings of cartilage within it hence preventing it from collapsing in case there is no air.

At the lower end, the trachea divides into the bronchi, which penetrate further into the lungs and divide repeatedly in to bronchioles. The bronchioles divide into many smaller tubes called alveolar ducts, which end in air sacs called alveoli, which are the respiratory surfaces of mammals.

Location of the lungs in the body

They are located in the thoracic cavity, enclosed by thoracic walls and diaphragm.



The mammalian lungs

They are elastic, spongy-like, located within the thoracic cavity and protected by the rib cage.
They are surrounded by pleural membranes that contain the pleural fluid, which prevents friction between the lung walls and the ribcage.
Between the ribs are intercostal muscles, which move the rib cage. Below the lungs is a muscular sheet of tissue called the diaphragm.
Inside each lung are many sac like structures called alveoli.

Mechanism of ventilation in mammals

Inspiration:

This is the process by which air is allowed into the respiratory organs (lungs).

- The external intercostal muscles contract while the internal intercostal ones relax.
- This makes the rib cage to move outwards and upwards.
- The diaphragm contracts and flattens.
- This increases the volume of the thoracic cavity and reduces the pressure in it below that of the atmosphere.
- This causes air to enter from the atmosphere through the nostril, trachea, bronchi, and bronchioles until it reaches the alveoli.

Expiration:

- The internal intercostal muscles contract and the external ones relax.
- This makes the rib cage to move downwards and inwards.
- The diaphragm relaxes and becomes dome-shaped.
- This reduces the volume of the thoracic cavity and increases its pressure beyond that of the atmosphere.

- This forces the lungs to contract and release Carbondioxide through the bronchioles, bronchi, trachea and out through the nostrils.

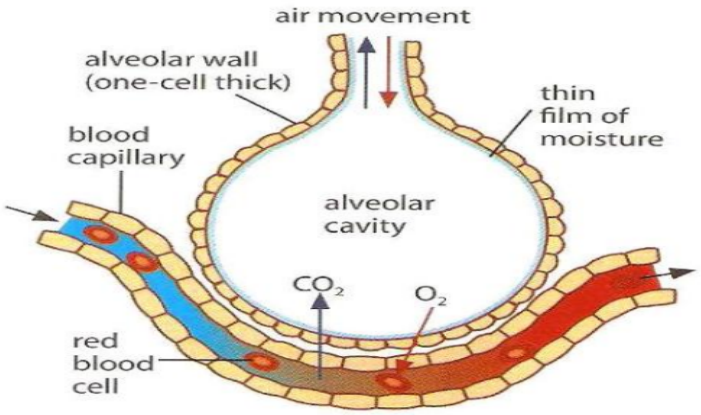
Gaseous exchange in the alveolus

This take place across walls of alveoli and blood capillaries by diffusion.

During inspiration, air is taken into the lungs filling the alveoli. This air contains much oxygen and little carbondioxide.

Oxygen in inspired air dissolves in the moisture of the alveolar wall and diffuses across this and capillary walls into the red blood cells of blood. Inside the red blood cell, oxygen combines with haemoglobin to form oxyhaemoglobin and carried in this form.

At the same time, CO_2 which was carried as bicarbonate ions in blood diffuses from blood through the capillary walls, across the alveolar wall into the alveolus. It then leaves the lungs in expired air.



Adaptations of the alveoli for gaseous exchange

1. They are thin walled, offering a short diffusion distance of gasses hence fast exchange.

2. They are numerous in the lungs, increasing the surface area for exchange of gasses by diffusion.

3. Each alveolus is supplied with a network of blood capillaries hence maintaining a high concentration.

4. Each alveolus is covered with a layer of moisture that dissolves the gasses, hence exchanged in solution form, increasing the rate of gaseous exchange by diffusion.

5. They are well ventilated ie have a fresh supply of fresh air, maintaining a high concentration gradient

Changes in the composition of gases in blood in capillaries across the alveolus

	Volume of gas carried by 100cc of blood	
Gas	**Blood entering lungs**	**Blood leaving lungs**
Nitrogen	0.9cc	0.9cc
Oxygen	10.6cc	19.0cc
Carbon dioxide	58.0cc	50.0cc

The blood that flows towards the lungs contains a larger volume of carbondioxide and less oxygen. But as it leaves the lungs, oxygen is added into it and some CO_2 is given off in the lungs. This indicates exchange of gases within the lungs.

Changes in approximate air composition during breathing

Component	Inhaled	Exhaled
Nitrogen	79%	79%
Oxygen	21%	17%
Carbon dioxide	0.03%	4%
Water vapour	Less saturated (variable)	Saturated
Temperature	Atmospheric temperature	Body temperature

- Because nitrogen plays no part in chemical reactions of the body, its composition remains the same in inspired and expired air.
- Inhaled air has more oxygen compared to exhaled air because it is taken up for the process of respiration, which produces CO_2. Hence exhaled air contains more CO_2 than inhaled air.

Experiment to demonstrate breathing in mammals

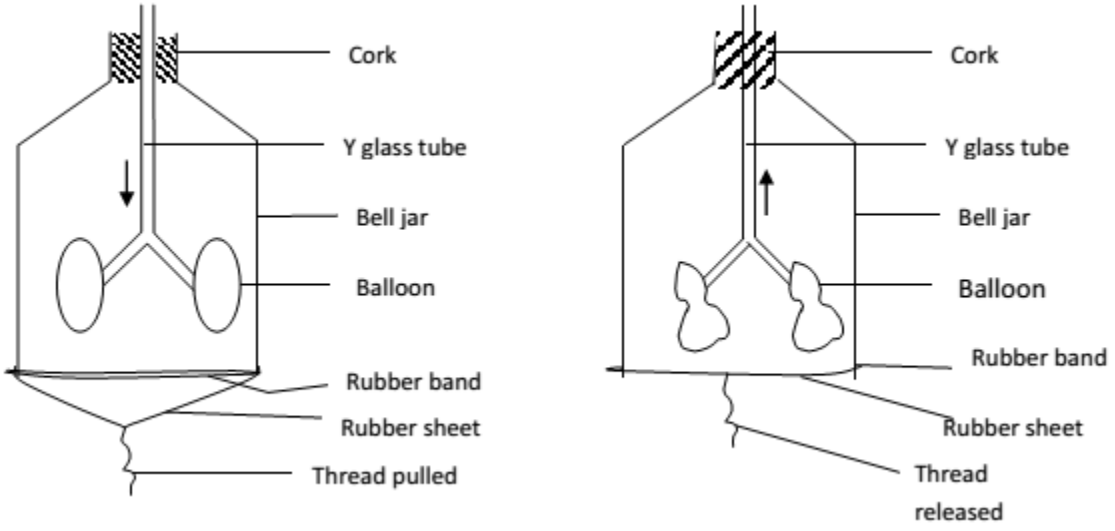
Materials

- Glass tubing,
- Cork,
- Rubber tubing,
- Y tube,
- Bell jar,
- Two balloons,
- Rubber sheet and
- Thread.

Procedure

- Get a bell jar and fix a cork with glass tubing in its mouth.
- Use a rubber tubing to connect a Y tube to the glass tubing inside the bell jar.
- Tie balloons on each end of the Y tube to act as lungs.
- Tie a rubber sheet using a rubber band at the open end of the bell jar to act as a diaphragm.
- Tie the end of a rubber sheet using a piece of thread.
- Pull the end of the rubber sheet using the thread to represent inhalation and release it to represent exhalation.

Setup



Observation

- When the thread is pulled, the rubber sheet stretches. This increases the volume in the bell jar and reduces the pressure. Air enters from out through the glass tube to the Y tube and inflates the balloons.
- When the thread is released, the rubber sheet returns to its normal flat shape. This reduces the volume in the bell jar and increases the pressure. Air is forced out of the balloons through the Y tube and glass tubing. This deflates the balloons.

Conclusion: Pulling of the thread represents inspiration and its release represents expiration.

Explanation

- The bell jar acts as the thoracic cavity and its walls as the rib cage.
- The glass tubing acts as the trachea and the ends of the Y tube act as the bronchi.
- The balloons act as the lungs
- Rubber sheet acts as the diaphragm

Important terms related with breathing.

Lung capacity: This refers to the total volume of air in the lungs when fully inflated. In an adult man, this is about 5 liters.

Tidal volume. It is the volume of air breathed in and out at rest.

Residual volume. It is the volume of air that remains in the lungs after maximum exhalation. Therefore, the lungs never get completely empty.

Experiment to show that expired air contains Carbondioxide.

Materials

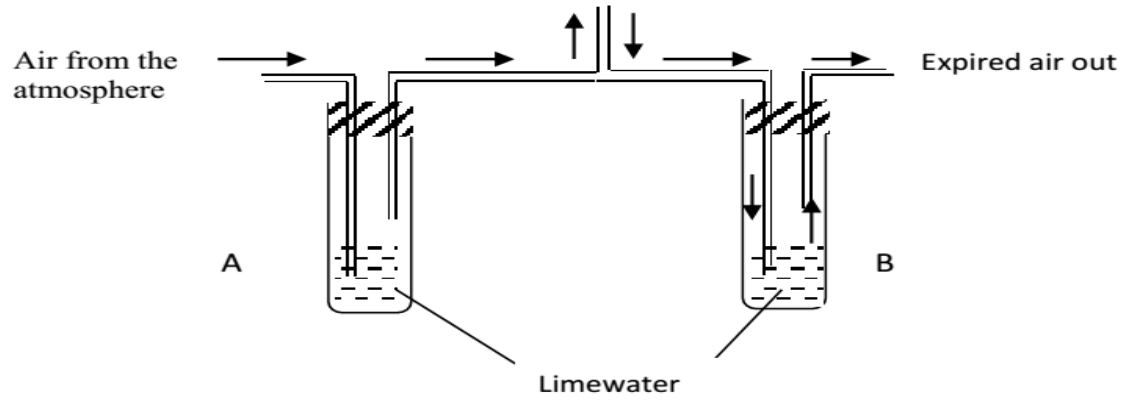
- Two test tubes,
- Two corks,
- T- Tube,
- Two right angled capillary tubes and
- Lime water

Procedure

- The apparatus are arranged as shown below.
- Place the T tube in the mouth and breathe in and out normally.

- Air is made to pass into the lungs from test tube A and out through test tube B.
- Inhaled air is got from the atmosphere through the capillary tube and lime water in tube A.
- Exhaled air passes through lime water and capillary tube in test tube B.

Set up of the experiment



Observation

Lime water in test tube B turns milky while that in A remains clear.

Conclusion

Expired air contains Carbondioxide.

Experiment to measure the volume of expired air/depth of breathing

Materials:

- Trough
- Calibrated Bell jar
- Cork
- Glass tube
- Rubber tube
- Water

Procedure:

- A bell jar calibrated in liters is completely filled with water and placed in a trough.
- One end of the rubber tube is then inserted in the bell jar while the other end is connected to a glass tube.
- The demonstrator (person) then breathes out once into the bell jar via the glass tube.
- This is done at two different occasions namely, at rest and immediately after an exercise.

Diagram of setup

(leave 8 lines for a diagram)

Observation:

- Some amount of water is displaced from the bell jar when the person breathes out.
- However, the volume of water displaced at rest is lower than the volume of water displaced after an exercise.
- The volume of water displaced is recorded and equal to the volume of air expired.

Conclusion:

The volume of expired air is greater immediately after an exercise than at rest, this shows that exercise increases the depth of breathing.
